Suppose you are a dispatcher and you have to manage an emergency. Which vehicle should you send?

- An ambulance and/or a helicopter?
- Which *precise* ambulance/vehicle?

Greedy approach : always send the vehicle which could arrive with the smallest among of time.

Is it a good idea?

- Send an helicopter for low priority emergencies.
- Obviously not optimal!

How to determine an optimal strategy?

 Natural framework to attack this problem : reinforcement learning (RL)

### Open questions

# RL : general framework

The goal of the agent is to find a policy  $\pi(a|s) = \mathbb{P}(a|s)$  which maximizes the *expected return* defined as

$$\mathbb{E}_{\pi}[\sum_{k\geq 0}\gamma^{k}R_{t+k+1}|S_{t}=s,A_{t}=a]$$

with  $\gamma \in [0, 1[$  and we call  $G_t := \sum_{k \ge 0} \gamma^k R_{t+k+1}$  the return.

We can also define the state-value function  $V_{\pi}$  as

$$V_{\pi}(s) = \mathbb{E}_{\pi}[\sum_{k\geq 0} \gamma^k R_{t+k+1} | S_t = s]$$

where  $s \in S$  is a state of the environment. Therefore we define the *action-value* function Q as

$$Q_{\pi}(s,a) = \mathbb{E}_{\pi}[\sum_{k\geq 0} \gamma^k R_{t+k+1} | S_t = s, A_t = a]$$

There are 3 different categories of RL depending on the possible interactions agent-environment.

- Online RL. The agent can interact with environment as he wants.
- **Off-policy RL.** The agent can interact with an environment but through a behaviour policy. He can only observe the result of a behaviour policy with the the environment.
- Offline RL. The agent can not interact with the environment. He only has access to a dataset which contains experiments of a behaviour policy.

How to determine the optimal policy  $\pi_{\star}$ ? Two main frameworks to attack real world problem.

- Q-learning
- Actor-critic

The idea of *Q*-learning is to learn the optimal *Q* function  $Q_{\pi_{\star}}$ . For example in DQN, they use a neural network to estimate this function. Idea : Directly parametrize the policy (typically by a neural network)

$$\pi_{ heta}(s|a) = \mathbb{P}[a|s, heta]$$

**Goal :** find  $\theta$  that maximizes a function  $J(\theta)$ . Which function can we choose? Depending on the context but typically something like

$$J( heta) = \mathbb{E}_{\pi_{ heta}}[\sum_{k=1}^{T} \gamma^k R_{t+k}] = \mathbb{E}_{\pi_{ heta}}[G_t]$$

How to maximize  $J(\theta)$ ? SGD ! How to compute the gradient ? Policy gradient Theorem

$$abla_ heta J( heta) = \mathbb{E}_{\pi_ heta} [
abla_ heta \log(\pi_ heta(S,A)) Q_{\pi_ heta}(S,A)]$$

How to estimate  $Q_{\pi_{\theta}}(s, a)$ ?

- Sampling (Mote-Carlo Policy Gradient REINFORCE)
   ⇒ High variance
- Estimate this action-value function with a neural network  $Q_w(s,a)\sim Q_{\pi_ heta}(s,a)$

This leads to the actor-critic algorithm In each iteration

- Updates action-value function parameters w
- Updates policy parameters  $\boldsymbol{\theta}$  in direction suggested by the critic.

# RL : Application to our problem

**Environment :** We could model our region with a graph. Each vertex will represent a given area of the region. There will be an edge between two vertices  $v_1$ ,  $v_2$  if we can drive from  $v_1$  to  $v_2$ . Furthermore, on all vertices  $v_i$  we could add some features (time, weather condition, temperature, traffic condition, ...).

**Actions :** At each emergency call the agent (our algorithm) will have to make some actions. Which precise vehicle should he send? Should he make a strategic move?

 $\ensuremath{\textbf{Rewards}}$  : We can imagine a lot of different function for the reward. For example

$$R_{t+1} = -\alpha_i t_r - \beta g(a, s) - c(a, s)$$

where *i* is the level of the emergency's priority,  $t_r$  is the time to arrive to the emergency location,  $\alpha_i$ ,  $\beta$  are hyperparameters, g(a, s) is a binary function which is one if we send an helicopter and zero otherwise and finally c(a, s) is the cost to make the strategic move chosen by the action *a*.

Our problem can be seen as a offline RL problem. But...

- In our problem, will we really want to maximize the *expected* reward?
- For example if we take  $\gamma = 0$  and suppose we are in a environment *s*. The agent could make two different actions  $a_1, a_2$ .
  - With action  $a_1$  he will get a reward of 100 with a probability of 0.8 and -100 with probability 0.2.  $\Rightarrow \mathbb{E}[G_t|a_1, s] = 60$
  - With actions  $a_2$  he will get a reward of 50 with probability 1.  $\Rightarrow \mathbb{E}[G_t | a_2, s] = 50$
- Thus the optimal policy π<sub>\*</sub> will choose the action a<sub>1</sub>, although it could lead to a potential bad situation with a quite high probability (0.2).
- Is it really a good idea in our problem?

# Risk-sensitive RL : general idea

In risk-sensitive RL the framework is similar to the classical RL.

But instead to try to maximize the expected return, we try to maximize a function

# $\mathcal{D}(G_t)$

called risk distortion.

The choice of the operator  $\ensuremath{\mathcal{D}}$  depends on the context. For example

• Exponential utility

$${\sf V}:=rac{1}{eta}\log\left(\mathbb{E}_{\pi}[e^{eta {\sf G}_t}]
ight).$$

With Taylor we have  $V = \mathbb{E}[G_t] + \frac{\beta}{2}Var(G_t) + O(\beta^2)$ 

• Conditional value at risk (CVaR $_{\alpha}$ )

$$\mathsf{CVaR}_{\alpha} = \mathbb{E}_{\pi}[\mathsf{G}_t | \mathsf{G}_t \le \mathsf{x}_{\alpha}]$$

where  $x_{\alpha}$  denotes the  $\alpha$ -quantile of  $G_t$ . i.e.  $x_{\alpha} := \inf\{x \in \mathbb{R} | \alpha \leq F_{G_t}(x)\}$ 

16/34

To resume, our problem is the following : we want to make offline risk-sensitive RL.

Good news :

• In the begin of this year [UCK21] present O-RAAC (Offline Risk Averse Actor-Critic) algorithm which solves this kind of problem.

We define

$$Z_{\pi}(s,a) :=_D G_t$$

and we denote  $\tau \mapsto Z_{\pi}(s, a; \tau)$  the quantile function of  $Z_{\pi}(s, a)$ . **Idea :** Use an actor-critic framework.

- The critic will be a neural network  $Z_{\pi}^{w}(s, a; \tau)$  which approximates  $Z_{\pi}(s, a; \tau)$ .
- The actor will be a neural network  $\epsilon_{\theta}$  which we will use to build the policy  $\pi_{\theta}$ .

#### Quantile regression

Let X a r.v. with distribution function F and probability density function f. Suppose that f is continuous and with  $supp(f) = \mathbb{R}$ . We pose  $x_{\tau}$  the  $\tau$ -quantile of X and

$$\rho_{\tau}(u) = (\tau - \mathbb{1}_{\{u \leq 0\}})u$$

Remark that since f is continuous, we get

$$x_{\tau} := F^{-1}(\tau)$$

#### Claim

$$x_{\tau} = \operatorname{argmin}_{q} \mathbb{E}[\rho_{\tau}(X - q)]$$

**Proof.** First remark that we have

$$\begin{split} \frac{\partial}{\partial q} \mathbb{E}[\rho(X-q)] &= \frac{\partial}{\partial q} \int_{\mathbb{R}} \rho_{\tau}(x-q) f(x) dx \\ &= \int_{\mathbb{R}} \frac{\partial}{\partial q} (\rho_{\tau}(x-q)) f(x) dx \end{split}$$

Image: Image:

æ

# Risk-sensitive RL : O-RAAC

and then

$$\begin{aligned} \frac{\partial}{\partial q} \mathbb{E}[\rho_{\tau}(X-q)] &= -\int_{-\infty}^{q} (\tau-1)f(x)dx - \int_{q}^{+\infty} \tau f(x)dx \\ &= \int_{\infty}^{q} f(x)dx - \int_{\infty}^{q} \tau f(x)dx - \int_{q}^{+\infty} \tau f(x)dx \\ &= F(q) - \tau = 0 \Rightarrow q = F^{-1}(\tau) \end{aligned}$$

And since

$$\frac{\partial^2}{\partial^2 q} \mathbb{E}[\rho_{\tau}(X-q)] = \frac{\partial}{\partial q} F(q) - \tau = f(q) > 0$$

we get as expected

$$x_{ au} = \operatorname{argmin}_{q} \quad \mathbb{E}[
ho_{ au}(X-q)]$$

イロト イヨト イヨト

æ

**Critic loss** How can we learn the quantile function ? First remark that

$$Z_{\pi}(s,a) =_D R(s,a) + \gamma Z_{\pi}(S',A')$$

Hence for a sampling (s, a, r, s', a') we can define the TD-error

$$\delta_{\tau,\tau'} = R(s,a) + \gamma Z_{\pi}^{w'}(s',a',\tau') - Z_{\pi}^{w}(s,a,\tau)$$

Moreover we define the  $\tau\text{-quantile Huber-loss}$ 

$$\mathcal{L}_k(\delta, au) = | au - \mathbb{1}_{\{\delta < 0\}}| \cdot \begin{cases} rac{1}{2k} \delta^2 & \text{if } |\delta| \le k \\ |\delta| - 2k & \text{otherwise} \end{cases}$$

With this function, we can define the critic loss

$$\mathcal{L}_{\text{critic}}(w) = \mathbb{E}_{\substack{(s,a,r,s') \sim d^{\beta} \\ a' \sim \pi_{\theta}(\cdot|s')}} [\frac{1}{NN'} \sum_{i=1}^{N} \sum_{j=1}^{N'} \mathcal{L}_{k}(\delta_{\tau_{i},\tau_{j}'};\tau_{i})]$$

23 / 34

Actor-loss

$$\mathcal{L}_{actor} = \mathbb{E}_{s \sim d^b(\cdot)}[\mathcal{D}(Z^w_{\pi_{ heta}}(s, \pi_{ heta}(s), au))]$$

Remark

$$egin{aligned} \mathcal{D}(Z^{m{w}}_{\pi_{ heta}}(s,\pi_{ heta}(s), au)) &= \int Z^{m{w}}_{\pi_{ heta}}(s,\pi_{ heta}(s), au) \mathbb{P}_{\mathcal{D}}( au) d au \ &\simeq rac{1}{K}\sum_{k=1}^{K}Z^{m{w}}_{\pi_{ heta}}(s,\pi_{ heta}(s), au_k) \end{aligned}$$

Acerbi's formula

$$\mathsf{CVaR}_lpha(Z^{w}_\pi(s,\pi(s), au)) = rac{1}{lpha}\int_0^lpha Z^w_\pi(s,s, au)d au$$

イロト イヨト イヨト

### Offline : controlling the bootstrap error.

In the offline setting the bootstrapping error appears : when evaluating the TD-error, the Z-value target will be evaluated at actions where there is no data.

How can we manage this problem?

- A few different ideas have been introduced to manage the error of the imitation policy.
- But with O-RAAC : learn a generative model (VAE, GAN)  $\pi^{IL}$  which imitates the behaviour policy.

Finally we pose

$$\pi_{ heta}(s) = b + \lambda \epsilon_{ heta}(\cdot|s,b)$$
 such that  $b \sim \pi^{IL}(\cdot|s)$ 

where  $\epsilon_{\theta}$  is a neural network trained with the actor-loss and  $\lambda$  an hyperparameter.

## Algorithm 1 O-RAAC

**Input**: Data set, Critic  $Z_w$  and critic-target  $Z_{w'}$ , VAE $_{\phi}$  Perturbation model  $\epsilon$ , modulation parameter  $\lambda$ , Distortion operator  $\mathcal{D}$  or distortion sampling distribution  $\mathbb{P}_{\mathcal{D}}$ , critic-loss parameters N, N', k, mini-batch size B, learning rate  $\eta$ , soft update parameter  $\mu$ .

for 
$$t = 1, ...$$
 do  
Sample *B* transitions  $(s, a, r, s')$  from dataset.  
Sample *N* quantiles  $\tau$  and *N'* quantile  $\tau'$  from  $\mathcal{U}(0, 1)$  and compute  
 $\delta_{\tau, \tau'}$   
Compute policy  $\pi = b + \lambda \epsilon(s, b)$  such that  $b \sim VAE(s, a)$ .  
Compute critic loss  $\mathcal{L}_{critic}(w)$ , actor loss  $\mathcal{L}_{actor}(\theta)$ , VAE loss  $\mathcal{L}_{VAE}(\phi)$ .  
Gradient state :  $w \leftarrow w - \eta \nabla \mathcal{L}_{critic}(w)$ ,  $\theta \leftarrow \theta - \eta \nabla \mathcal{L}_{actor}(\theta)$ ,  $\phi \leftarrow \phi - \eta \nabla \mathcal{L}_{VAE}(\phi)$ .  
Perform soft-update on  $w' \leftarrow \mu w + (1 - \mu)w'$ .  
end for

Did we solve our problem ?

O-RACC is tested on datasets provided by OpenAI.

For example Half Cheetah dataset has the following parameters.

- Action space  $\mathbb{R}^6$ .
- Environment space  $\mathbb{R}^{17}$ .
- Millions of samples.

In our problem :

- Environment space is huge!
- Not a lot of samples.
- A lot of state-action will be unobservable.

# Introduction

## **2** Reinforcement learning (RL)

General framework Actor-critic Application to our problem

#### 8 Risk-sensitive RL

General idea Offline Risk Averse Actor-Critic (O-RAAC)

### Open questions

< 1 k

Is this hopeless?

- No fully confident answer to this question.
- But we believe we could solve it.
- [NKL18] solves almost the same problem with less data.

In [NKL18] they use Multi-agent RL to solve a problem similar to our : they try to determine the optimal real-time location of the police patrol to minimize the response time to an emergency.

- Each patrol is seen as a agent which has access only at a local observation.
- Data : time and zone of incident (24 possibilities) for 31 days.
- Not risk-sensitive.

This paper leads to an idea to solve our problem :

- Reduce the size of the environment and using a multi-agent approach. Each vehicle would have access at a local representation of the environment.
- Limitation : not an optimal uses of all data.

Does it really help?

30 / 34

#### How to reduce the environment space?

Observation : we are close to the few-shot learning problem.

Idea : use methods develop for few-shot learning.

For example : use a neural network  $\phi_{\theta}$  to encode the environment states *s*. After that apply O-RAAC algorithm to  $\phi_{\theta}(S)$  environment. How to learn  $\phi_{\theta}$ ?

- Idea : two states which lead to the same action will be encode closely.
- For a state *s* take two others action *s*<sub>+</sub> and *s*<sub>-</sub> where *s*<sub>+</sub> will lead to the same action *a* as *s* and *s*<sub>-</sub> to another. After that we define the loss as

$$\mathcal{L}(\boldsymbol{s}, \boldsymbol{s}_+, \boldsymbol{s}_-) = \max\{\|\phi_{ heta}(\boldsymbol{s}) - \phi_{ heta}(\boldsymbol{s}_+)\|^2 - \|\phi_{ heta}(\boldsymbol{s}) - \phi_{ heta}(\boldsymbol{s}_-)\|^2 + lpha, \boldsymbol{0}\}$$

#### How to add samples in our dataset?

We could add synthetic data to our dataset.

Emergencies are independent of our policy !

But it could be costly to build and some errors would be unavoidable. How to deal with?

- Generative Teaching Network ([SRL+20])?
- Could we determine a method to add data only to *important* (*s*, *a*, *r*, *s'*) cases ?
- Core-set selection : This problem considers a fully labeled dataset and tries to choose a subset of it such that the model trained on the selected subset will perform as closely as possible to the model trained on the entire dataset.

#### Other ideas.

- Transfer learning?
